ABSTRACT

Visceral and subcutaneous adipose tissue display important metabolic differences that underline the association of visceral obesity with obesity-related cardiovascular and metabolic alterations. Recently, the potential role of adipokines (visfatin and retinol binding protein-4) in the development of obesity-related insulin resistance are increasingly understood. The aim of the present study was to investigate whether plasma visfatin and retinol binding protein-4 (RBP-4) levels are correlated with obesity and type 2 diabetes mellitus and to examine their association with visceral, subcutaneous as well as fat deposition in the liver. The study was conducted on forty patients with type 2 diabetes mellitus and twenty age and sex matched healthy subjects as controls. Both diabetic and control subjects were divided into two equal groups according to the body mass index (BMI), the first was non-obese subjects with BMI < 25 Kg/ m^2 and the other was obese subjects with BMI ≥ 30 Kg/m^2 (20 cases each). After full clinical evaluation, fasting plasma glucose, glycosylated hemoglobin, and lipid profile levels were estimated in all groups. Plasma visfatin, retinol binding protein-4 and serum insulin levels were measured by enzyme-linked immunosorbent assay. Insulin resistance index was calculated by the homeostasis model assessment ($HOMA_{IR}$). Visceral fat, subcutaneous fat and fat deposition in the liver were measured by ultrasonography. The results of the study showed that the levels of plasma visfatin and RBP-4 were increased significantly in diabetics compared to control group; moreover, both of them were significantly higher in diabetics compared to control subjects with similar BMI values. However, Plasma visfatin concentration was positively correlated with RBP-4, BMI, waist / hip ratio (WHR), insulin, insulin resistance index and visceral fat area, while it was negatively correlated with systolic blood pressure in all diabetic patients (both obese and non-obese). On the other hand, plasma RBP-4 concentration was correlated positively with visfatin, BMI, WHR, blood glucose, insulin and insulin resistance index, and ectopic fat deposition in the liver in diabetic patients. Stepwise multiple regression analysis revealed that plasma visfatin levels remained positively correlated with visceral fat area and WHR; while plasma RBP-4 levels remained positively correlated with BMI, ectopic fat deposition in the liver and $HOMA_{IR}$ in all diabetic patients. Plasma visfatin levels were significantly higher in diabetics than control subjects and positively correlated with visceral fat area but not with subcutaneous fat.

Although visfatin levels were increased in type 2 diabetes mellitus, the correlation seems to be primarily through obesity. Moreover, plasma RBP-4 levels were increased significantly in diabetics compared to control subjects. However, circulating RBP-4 is not correlated with the amount of visceral or subcutaneous fat, but, it was correlated positively with ectopic fat deposition in the liver and insulin resistance. Thus, the close relationship between circulating RBP-4 with ectopic fat deposition in the liver and insulin resistance may reflect stronger effects of RBP-4 on hepatic insulin sensitivity.

INTRODUCTION

An increased adipose tissue mass is strongly associated with the pathogenesis of insulin resistance and type 2 diabetes[1] .Besides its role in energy storage, adipose tissue, an endocrine organ, produces several hormones and cytokines (such as leptin, tumor necrosis factor-α, interleukin-6, and adiponectin) that have wide-ranging effects on carbohydrates and lipid metabolism, and therefore appear to play an important role in the pathogenesis of diabetes, insulin resistance and atherosclerosis[2]. However, it is apparent that accumulation of visceral adipose tissue has a greater cardio-metabolic risk than subcutaneous adipose tissue, even though subcutaneous adipose tissue depot was the largest of the two[3]; removal of visceral than subcutaneous tissue improves insulin sensitivity[4]. Additionally, differences in gene expression between adipocytes of visceral or subcutaneous origin do exist. The potential role of recently discovered adipokines (visfatin and retinol binding protein-4) in the development of obesity- related insulin resistance are increasingly understood.

Visfatin was recently identified as a protein highly expressed in visceral adipose tissue compared to subcutaneous adipose tissue[5], previously known as a pre-B-cell colony-enhancing factor (PBEF), has a function also in the immune system, where it was described as a growth factor for early B-cells[6]. Visfatin (PBEF) binds and activates the insulin receptor in different insulin-sensitive cells in vitro and treating mice with recombinant visfatin elicited insulin-like effects, also in vivo. Plasma glucose is lowered by treatment with visfatin, while heterozygous mice knockout for the visfatin gene have plasma glucose levels higher than wild-type littermates[5]. Visfatin expression in adipocytes is upregulated by dexamethazone and is downregulated by growth hormone, isoproterenol, and cholera toxin. Insulin has no effect on visfatin mRNA [7]. Moreover, visfatin is upregulated by peroxisome proliferators-activated receptor (PPARα and PPARγ) agonists in obese rats in association with improved glycaemic control and lipid profile, thus suggesting that PPARα and PPARγ agonists may act, at least in part, through the upregulation of visfatin expression [8]. A recent study in humans reported plasma visfatin to be directly correlated with body mass index and body fat content in males only and failed to find a different

expression of visfatin mRNA between visceral and subcutaneous fat depots [9].Although, plasma levels of visfatin increased with obesity and correlated positively with visceral adiposity [10], others did not notice that association[9].

Retinol-binding protein (RBP)-4, secreted by liver and adipocytes, has important effects on systemic insulin sensitivity and glucose homeostasis[11]. Serum RBP-4 levels are elevated in insulin resistant states both in mice and humans. In mice, intraperitoneal injection of recombinant human RBP-4 induces systemic insulin resistance. Treatment of insulin-resistant mice with rosiglitazone, peroxisome proliferators activated receptor PPARγ agonist that improves insulin sensitivity, completely normalizes elevated RBP-4 levels and reverses insulin resistance[12]. Elevation of RBP-4 might therefore play a causative role in insulin resistance and type 2 diabetes mellitus. In humans, serum RBP-4 levels correlate with the magnitude of insulin resistance and components of the metabolic syndrome. Improvement of insulin sensitivity by exercise training is associated with a reduction in serum RBP-4 levels[11]. Recently, serum RBP-4 levels were shown to be strongly correlated with the trunkal obesity and not with peripheral obesity[13]. However, Stefan et al.[14] did not show any correlation between RBP-4 and either visceral or subcutaneous fat.

Effective methods for assessing visceral fat are important to investigate its role in the increased health risks in obesity. Simple anthropometric methods, such as waist-to-hip circumference ratio, waist circumference or sagittal diameter are widely used. However, these methods cannot differentiate between visceral and subcutaneous fat and are less accurate[15]. Dual energy x-ray absorptiometry (DEXA) measures body mass index, percentage of fat and total body fat mass[16].There have been a considerable number of researches involved in determining each component of body fat mass and body fat distribution. These methods are computerized tomography (CT)[17] and magnetic resonance imaging (MRI)[18] the latter made it possible to assess subcutaneous fat (SF), and visceral fat (VF) area. However, they are expensive, time consuming and require a relatively high radiation dose[16]. Moreover, in 1992, the method using abdominal ultrasonography (US) for assessment of subcutaneous fat thickness was reported, which made it possible to assess abdominal fat distribution in each individual frequently and repeatedly[19].Ultrasonography is a new, simple and accurate method of measuring visceral fat area. Moreover, it can differentiate subcutaneous from visceral fat area[20].

The main objectives of the current study were to investigate the role of visfatin and retinol binding protein 4 in type 2 diabetes mellitus and obesity and to measure the visceral and subcutaneous abdominal fat as well as ectopic fat deposition in the liver using ultrasound, and whether these measures would be correlated with plasma visfatin and RBP-4.

MATERIAL & METHODS

A total of forty patients with type 2 diabetes mellitus (19 males and 21 females, with a mean age of 50.3 ± 3.8 years and a duration of diabetes of 6.0 ± 3.2 years) were recruited from Internal Medicine Outpatient Clinics at Kasr El-Aini Hospital, as well as forty normal healthy adults (20 males and 20 females, with a mean age of 50.2 ± 3.6 years) from medical and paramedical staff personals participated as control group. An informed consent was taken from all participants. The subjects chosen for the study were categorized based on their body mass index (BMI) as non-obese (BMI < 25 kg/m2) and obese (BMI ≥30 kg/m^2). Obesity was defined according to the World Health Organization criteria on the basis of the body-mass index (BMI) (the weight in kilograms divided by the square of the height in meters)[21]. Diagnosis of type 2 diabetes mellitus was made according to the American Diabetes Association. They considered an individual to be diabetic if fasting plasma glucose (FPG) was ≥ 126 mg/dl and/or taking treatment for diabetes[22]. Additionally, in the current study first and second degree relatives of type 2 diabetic patients were excluded from the control group. The diabetic patients were treated with diet and the oral hypoglycaemic drug metformin or sulfonylurea. No patients were receiving thiazolidinediones or insulin. Patients who had a diagnosis of urinary tract infection, urolithiasis, liver cirrhosis, hypertension, ischemic heart disease, macrovascular disease, overt proteinuria, or other known major diseases were excluded from the study.

The following investigations were performed for all subjects:

Detailed history taking and physical examination to exclude the presence of cardiac, hepatic, renal, gastrointestinal or malignant disease which might affect the parameters to be investigated. Blood pressure was measured to exclude the presence of hypertension. Anthropometric measurements including: Body mass index (BMI) and Waist to hip ratio (WHR) were calculated for each participant. Waist and hip circumferences were measured. The waist circumferences were measured to the nearest 0.1 cm at the narrowest point between the lowest rib and the uppermost lateral border of the right iliac crest. The hips were measured at their widest point.

Biochemical analysis

Venous blood samples were collected after 12 hour overnight fast from all subjects and divided into parts. Part of blood sample was withdrawn on K_2EDTA for plasma separation and the separated plasma was kept frozen at – 80°C for further determination of Visfatin, Retinol-binding protein-4, and insulin. The other part was taken as whole blood on K_2EDTA for determination of glycosylated hemoglobin (HbA_{1c}) by spectrophotometic method using kit provided by Stanbio, Texas, USA[23]. The third part was allowed to clot. The separated serum was used for determination of triacylglycerol[24]; total cholesterol[25], high density lipoprotein cholesterol (HDL-c) and low density lipoprotein cholesterol (LDL-c)[26] using commercially

available kits. The last part was collected on fluoride for estimation of fasting plasma glucose by glucose oxidase-peroxidase method[27]. Fasting plasma insulin was assessed by the ELISA kit provided by BioSource, Nivelles, Belgium. Plasma visfatin levels were estimated by the ELISA kit provided by Phoenix Pharmaceuticals, Belmont, CA, USA. Assay sensitivity was 2 ng/ml and inter-assay and intra-assay Coefficient Variation (CV) were <10% and <5% respectively. Plasma Retinol-binding protein 4 levels (RBP-4) were measured by the ELISA kit provided by BioSource, Nivelles, Belgium. Assay sensitivity was between 0.001 and 5 μg/ml with inter-assay and intra-assay CV 5 % - 4.6 % respectively. Insulin sensitivity was calculated using the homeostatic model assessment ($HOMA_{IR}$) index with the formula: fasting plasma glucose (mmol/l) × fasting plasma insulin (μIU/ml) / 22.5[28].

Body fat distribution

Thirty seven subjects were examined by US machine (Siemens, Elegra) and forty three subjects were examined using (General Electric, voluson pro) US machine. Screening of the abdomen was done for assessment of the liver for presence of fatty changes, and then visceral fat thickness in different sites and subcutaneous fat were measured by two experienced sonographers while the patient was in the supine position during normal quite respiration.

A 3.5–5 MHz convex-array probe was used to measure the first three parameters. The distance between the abdominal muscles and the splenic vein was scanned transversely in the mid line. In some cases of obese participants, the splenic vein was unclear in the mid line due to increased visceral fat in the mid line, so we tried to take that measurement in the anterior axillary line searching for the splenic vein at the splenic hilum. When the splenic vein could not be visualized clearly, that vein was detected by using color Doppler flow (Figure 1). The distance between the abdominal muscles and posterior wall of the aorta was measured; also, transversely in the mid line on the umbilicus (Figure 2).The thickness of the fat layer of the posterior right renal wall was scanned longitudinally in the right anterior axillary line (Figure 3). For the fourth measurement (the thickness of the subcutaneous fat), it was measured using 7.5 MHz linear-array probe. The volume of visceral fat was measured according to the following equation quoted from Hikoora et al: Visceral fat area (VFA) = -9.008+1.191 x (The distance between the internal surface of the abdominal muscle and the splenic vein) + 0.987 x (The distance between the internal surface of the abdominal muscle and the posterior wall of the aorta on the umbilicus in mm) + 3.644 x (thickness of the fat layer of the posterior right renal wall in mm)[20] .The visceral fat area of over 100 cm^2 is widely accepted in diagnosing visceral fat obesity[15].

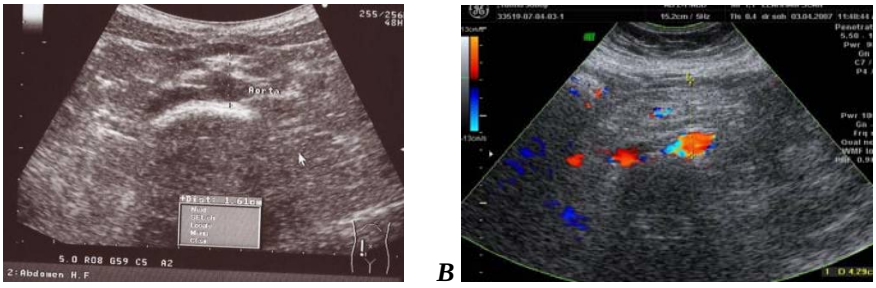
Figure 1: A- shows measuring the distance between splenic vein and abdominal wall muscles in mid line. B- Measurement in anterior axillary line, both are comparable.



A ***B***

Figure 2: Measurement of visceral fat from abdominal muscles to posterior aortic wall. A. In non obese control. B. Complementary color Doppler is used in that case (obese control) for better visualization of the aorta.

Figure 3: Showing measurement of posterior renal fat (arrow) in obese female diabetic patient. Note also the presence of enlarged liver with bright echopattern (fatty liver).

Statistical analysis

Statistical Package for social science (SPSS) program version 9.0 was used for analysis of data. Data was summarized as mean ± SD. t- test was used for analysis of 2 quantitative data. One way ANOVA was done for analysis of more than two variables followed by post HOC test for detection of significance. Simple linear correlation (Pearson's correlation) was used for quantitative data. It was done to detect the relation between the Visfatin and RBP-4 with all other demographic and laboratory data. "r " value was considered weak if <0.25, mild if ≥0.25-<0.5, moderate if ≥ 0.5 -< 0.75 and strong if ≥0.75[29]. Stepwise multiple regression analysis was done for detection of independent determining factors for visfatin and RBP-4 levels. P-value is considered significant if ≤ 0.05*.

RESULTS

The clinical characteristics of the study groups (mean ± SD) are shown in table 1. A total of 40 patients with type 2 diabetes mellitus and 40 sex and age matched nondiabetic subjects were studied. Diabetic patients had significantly higher mean values of fasting plasma glucose (FPG), insulin, $HOMA_{IR}$, total cholesterol, triacylglycerol, LDL-c, uric acid, HbA_{1c} and systolic blood pressure (SBP) than those of control subjects. While, mean values of HDL-c were significantly lower in diabetics than control subjects. The mean value of plasma visfatin levels was found to be significantly higher in diabetic patients compared to control subjects (44.1 ± 13.4 *vs.* 32.8 ± 14.7 ng / ml, p<0.001 respectively) as well as plasma RBP-4 (46.3 ± 10.3 *vs.* 26.8 ± 7.5 µg/ml, p< 0.001 respectively). As regards visceral fat area (VFA), the mean value was significantly higher in diabetic patients than in control subjects (95.2 ± 15.6 *vs.* 83.3 ± 21.4 cm^2, p<0.006). However, no significant difference was found between diabetic and control subjects in age, BMI, WHR, diastolic blood pressure (DBP), and subcutaneous fat (SF) thickness (13.7 ± 6.1 *vs.*11.8 ± 4.5 mm, p>0.1). No gender differences were observed in any of the studied parameters with mean plasma visfatin levels in diabetics were 44.7 ± 12 in males *vs.* 43.6 ± 14.9 ng / ml in females, p> 0.8) and in control subjects were 30 ± 11.1 in males *vs.* 35.2 ± 17.2 ng /ml in females, p > 0.3). Mean plasma RBP-4 levels in diabetics were 46.4 ± 10 in males *vs.* 46.1 ± 10.7 µg/ml in females, p > 0.9) and controls were 26.7 ± 6.4 in males *vs.* 26.9 ± 8.5 µg/ml in females, p > 0.9).

HDL-c: High density lipoprotein cholesterol
LDL-c: Low density lipoprotein cholesterol
HbA_{1C}: Glycosylated hemoglobin RBP-4: Retinol binding protein 4

Table 2 shows that there was a significantly higher mean value of visfatin levels in diabetic groups as compared to that in control groups ($p< 0.001$). Furthermore, mean visfatin levels were significantly higher in diabetic patients compared with controls with similar BMI values ($p< 0.001$), while mean values of plasma RBP-4 level of non-obese and obese diabetics were significantly higher in comparison to non-obese and obese control group respectively ($p< 0.001$). Moreover, mean RBP-4 level of obese diabetic participants was, also, significantly higher than that of non-obese diabetic group ($p< 0.001$). There were significant differences in the mean values of blood lipid profile, systolic blood pressure, and $HbA_{1c,}$ levels between diabetics and controls. Mean value of cholesterol levels in non-obese and obese diabetic patients was significantly higher than that in control group with similar BMI respectively ($p< 0.001$), but there was no significant difference between non-obese and obese diabetics. Mean values of triglyceride levels was significantly higher in both obese and

non-obese diabetics when compared to non-obese controls, while; no significant difference was observed between obese control and both diabetics (obese and non-obese) and non-obese controls. The mean values of fasting insulin levels as well as $HOMA_{IR}$ were significantly different among the four studied groups ($p< 0.001$). The mean value of fasting plasma glucose levels in diabetics was significantly higher than that in control groups with similar BMI, and there was a significant difference between non-obese and obese diabetic ($p< 0.001$). As regards BMI, WHR, visceral fat area and subcutaneous fat thickness, there were significant differences between obese and non-obese groups in both diabetics and control subjects. But there were no significant differences neither between obese diabetics and obese control nor non-obese diabetics and non-obese control; except for there was a significantly higher visceral fat area in non-obese diabetics compared to non-obese control group. However, no significant difference was observed between groups and the rest of the studied parameters.

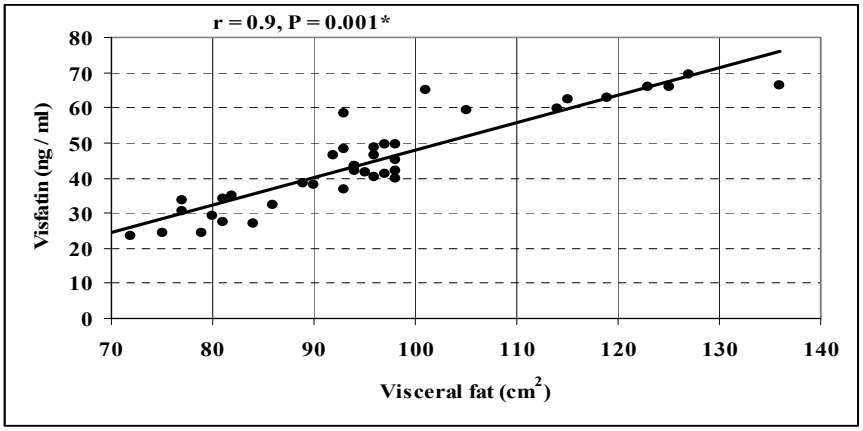

Figure 4: Correlation between plasma visfatin and visceral fat area in diabetic patients.

Pearson correlation analysis was used to identify the factors that most closely related to visfatin and RBP-4 in diabetic patients as shown in table 3. Plasma visfatin levels were correlated positively with RBP-4, BMI, WHR, insulin, and $HOMA_{IR}$ (respectively, $r = 0.4$, $p< 0.02$; $r = 0.8$, $p< 0.001$; $r = 0.9$, $p< 0.001$; $r = 0.5$, $p< 0.003$; $r = 0.5$, $p< 0.002$) and visceral fat area ($r = 0.9$, $p< 0.001$) Figure 4; whereas it was negatively correlated with SBP ($r = -0.3$, $p< 0.04$). There was no significant correlation between plasma visfatin and the rest of the studied parameters. Plasma RBP-4 levels were correlated positively with visfatin ($r = 0.4$, $p< 0.02$), BMI ($r = 0.5$, $p< 0.002$), WHR ($r = 0.4$, $p< 0.006$), FPG ($r = 0.4$, $p< 0.01$), insulin ($r = 0.4$, $p< 0.004$), $HOMA_{IR}$ ($r = 0.6$, $p< 0.001$) and fatty liver ($r = -0.7$, $p< 0.001$). There was no significant correlation between plasma RBP-4 and age, sex, duration of diabetes, blood pressure, lipid profile, HbA_{1c}, visceral fat area, and subcutaneous fat.

BMI: Body mass index WHR: Waist hip ratio SBP: Systolic blood pressure
DBP: Diastolic blood pressure FPG: Fasting plama glucose SF: Subcutaneous fat
HOMA$_{IR}$: Homeostatic model assessment of insulin resistance
HDL-c: High density lipoprotein cholesterol LDL-c: Low density lipoprotein cholesterol
HbA$_{1C}$: Glycosylated hemoglobin RBP-4: Retinol binding protein 4

When each group was analyzed separately, in diabetic obese group plasma visfatin levels were correlated positively with RBP-4 ($r = 0.5$, $p< 0.03$), BMI ($r = 0.8$, $p< 0.001$), WHR ($r = 0.9$, $p< 0.001$), and VFA ($r = 0.8$, $p< 0.001$). Plasma RBP-4 levels were correlated positively with visfatin ($r = 0.5$, $p< 0.03$), $HOMA_{IR}$ ($r = 0.5$, $p< 0.05$) and fatty liver ($r = 0.7$, $p< 0.001$). In non-obese diabetic group, plasma visfatin levels were correlated positively with insulin ($r = 0.4$, $p< 0.05$) and visceral fat only ($r = 0.9$, $p< 0.001$), while plasma RBP-4 levels were correlated positively with insulin ($r =0.5$, $p< 0.04$), $HOMA_{IR}$ ($r = 0.6$, $p< 0.002$) and fatty liver ($r = 0.9$, $p< 0.001$).

While in control group, plasma visfatin levels were correlated positively with RBP-4, BMI, WHR, FPG, insulin, $HOMA_{IR}$, and VFA (respectively, $r = 0.6$, $p< 0.001$; $r = 0.9$, $p< 0.001$; $r = 0.9$, $p< 0.001$; $r = 0.6$, $p< 0.001$; $r = 0.8$, $p< 0.001$; $r = 0.8$, $p< 0.001$; ; $r = 0.9$, and $p< 0.001$). Plasma RBP-4 levels were

correlated positively with visfatin (r = 0.6, p< 0.001), BMI (r = 0.6, p< 0.001), WHR (r = 0.6, p< 0.001), FPG (r = 0.5, p< 0.01), insulin (r = 0.7, p< 0.001) (Figure 5), $HOMA_{IR}$ (r = 0.7, p< 0.001) and fatty liver (r = 0.7, p< 0.001). In obese control group, plasma visfatin levels showed significant positive correlation with BMI (r =0.6, p< 0.006), WHR (r =0.7, p<0.001) and visceral fat (r=0.8, p<0.001).While, plasma RBP-4 levels were positively correlated with fatty liver only (r =0.7, p<0.001). However, in non-obese control group, plasma visfatin levels were correlated positively with visceral fat only (r = 0.7, p< 0.001). Plasma RBP-4 levels were correlated positively with fasting insulin levels (r = 0.6, p< 0.001) and $HOMA_{IR}$ (r = 0.6, p< 0.001) in non-obese control subjects.

Table 4 shows stepwise multiple regression analysis using plasma visfatin as independent variable and various clinical and biochemical parameters as dependent variables in diabetic patients, only plasma visfatin level remained positively correlated with visceral fat area (VFA) and WHR. When each group was analyzed separately, plasma visfatin level remained, also, positively correlated with visceral fat and WHR in obese diabetic group (p = 0.001, in both) and only with visceral fat in non-obese diabetic group (p < 0.001). In control group, plasma visfatin was positively correlated with visceral fat (p < 0.001), even after separation into obese and non-obese groups.

Stepwise multiple regression analysis using plasma RBP-4 as an independent variable and various clinical and biochemical parameters as dependent variables in diabetic patients, showed that fatty liver (p < 0.001), BMI (p < 0.001) and insulin resistance (p < 0.05) were positively associated with plasma RBP-4, and only fatty liver was positively correlated with RBP-4 in both obese and non-obese diabetic groups, separately. However, in control group, plasma RBP-4 was positively correlated with fatty liver (p <0.001) and $HOMA_{IR}$ (p <0.04), and with fatty liver only (p < 0.001) in obese control group and with insulin only (p < 0.009) in non-obese control group.

DISCUSSION

Type 2 diabetes mellitus is characterized by target-tissue resistance to insulin. It is strongly linked to obesity as over 80% of diabetics are obese [(30)]. Insulin resistance is the core pathogenic factor for diabetes. In addition, it is, also, strongly associated with obesity, hypertension and cardiovascular disease[(30)]. The new adipocytes derived hormones visfatin and retinol binding protein-4 (RBP-4) may be an important link between increased fat mass and insulin resistance and disorder of glucose metabolism in diabetes. To investigate whether the levels of visfatin, a recently characterized peptide, and the fat derived factor RBP-4 are related to adiposity and serve as determinants of insulin sensitivity in diabetic and obese subjects, the present study was conducted to examine the relationship between plasma visfatin and RBP-4 and body composition, abdominal fat distribution, and insulin sensitivity in type 2 diabetes mellitus and obesity.

Visfatin corresponds to pre-B cell colony–enhancing factor, a 52-kDa cytokine secreted by activated lymphocytes[(6)] and is up-regulated in neutrophils and monocytes after exposure to inflammatory stimuli[(31-33)]. Previous reports have raised questions regarding the origin and clinical relevance of visfatin, as it is ubiquitously expressed in different cell types[(31, 34-40)]. However, recent studies support the view that visfatin is a true adipokine that is clearly

expressed in human adipocytes[33,41,42]. It was, also, shown that hyperglycemia induced visfatin overexpression in cultured human adipocytes[41]. There have been contradictory findings on the association between visfatin and obesity. Haider et al.[43] showed that visfatin levels were substantially increased in morbidly obese individuals and gastric banding surgery lowered the circulating visfatin levels in them. However, a recent study showed that the plasma levels of visfatin were significantly lower in obese subjects[42]

In the current study, it was found that plasma visfatin levels were significantly higher in the diabetics compared with obese and non-obese control subjects. Furthermore, visfatin levels in obese diabetics were significantly higher compared to non-obese diabetics. Similar findings were reported in a previous study[39], which had suggested that the increased circulating levels and messenger RNA expression of visfatin in the diabetic subjects may be related to their increased adipose tissue mass. Also, the present study demonstrated that plasma visfatin levels showed a significant positive correlation with BMI and waist / hip ratio. This finding supports the studies of Berndt et al[9] and Haider et al.[43] who reported that visfatin is associated with obesity.

Visfatin is preferentially secreted by visceral fat cells and increased in obesity and type 2 diabetes mellitus[5]. This is considered to reflect an impairment of visfatin signaling or a dysregulation in its biosynthesis[5,7]. Visfatin levels correlate with visceral adipose tissue[5,9] and consequently any increase in visfatin could indicate an increased visceral fat mass, which is usually associated with insulin resistance. Thus, considering the insulin mimetic properties of visfatin, the increase in visfatin might be regarded as compensation for decreased insulin mediated glucose uptake, eventually by increased GLUT-4 transcription. Along this line, the present study showed a significant positive correlation between visfatin and $HOMA_{IR}$, as well as insulin levels in the diabetic group in simple regression analysis but not in multiple regression analysis. This finding is in accordance with the study of Chen et al.[10] who showed a significant association between visfatin and $HOMA_{IR}$, and in contrast to other studies that showed a lack of association between visfatin and insulin resistance[9,44]. Only visceral fat area remained significantly associated with plasma visfatin level in multiple regression analysis in all the studied groups. On the other hand, plasma visfatin did not correlate with BMI or other biomarkers such as, blood pressure and lipid profiles parameters in a multiple regression analysis. These facts are consistent with findings[10] that visfatin is mainly secreted in the visceral fat and not subcutaneous fat, and may suggest that the pathogenetic mechanism of visfatin in type 2 diabetes mellitus is different from that of insulin resistance.

RBP-4 is another factor derived from fat cells, has recently been reported to provide a link between obesity and insulin resistance modulating glucose homeostasis and

therefore possibly involved in the development of insulin resistance[12]. RBP-4 expression is increased in the adipose tissue of adipose-glucose transporter 4 (GLUT4) knockout mice and the serum levels of RBP-4 are elevated in insulin-resistant mice[12].

The current study extends the research on RBP-4 to humans and showed a correlation between RBP-4 levels and the magnitude of insulin resistance in subjects with obesity, and type 2 diabetes mellitus. In the present study, plasma RBP-4 levels were significantly higher in diabetic group when compared to control subjects. Moreover, RBP-4 levels were positively correlated with body-mass index, and waist-to-hip ratio. This is in agreement with the recent study of Graham et al.[11] who found a significant increase in RBP-4 in type 2 diabetics and obese subjects, and, also, found that the elevated RBP-4 levels correlate positively with components of the metabolic syndrome such as body mass index, waist circumference, triacylglycerol, and systolic blood pressure. Also, this is in accordance with the previous study of Yang et al.[12] who showed an unequivocal difference between normal and obese subjects, with or without diabetes, in terms of circulating RBP-4 concentrations. They found that it was significantly higher in obese diabetics compared to lean diabetics and non-diabetic. On the contrary to these findings, Cho et al.[45] found that glucose tolerance status had only a slight effect on plasma RBP-4 concentrations. This is probably attributable to the narrow BMI range shown by their study subjects. This was, also, in disagreement with Janke et al., [46], who found that RBP-4 gene expression in adipose tissue was significantly reduced in obese subjects. They, also, detected no difference in RBP-4 serum levels between lean, overweight, and obese subjects[46]. The present study, also, showed that RBP-4 was correlated with insulin resistance even in non-diabetic subjects. These results indicate that RBP-4 could be used as an index of insulin sensitivity. The present findings regarding the relationships of circulating RBP4 with insulin resistance are consistent with previous reports[11,14]. However, other studies did not find significant relationship between them[46].

The RBP-4 gene is located on chromosome 10q24 in humans in a region contains at least one interesting candidate gene, hexokinase 1, the gene encoding a key enzyme in the initial step of glucose metabolism[47]. Furthermore, increased serum RBP-4 levels are known to stimulate hepatic gluconeogenesis through stimulation of phosphoenolpyruvate carboxy-inase[12]. Study data from Cho and colleagues[45] demonstrated elevated RBP-4 levels in patients with impaired glucose tolerance and type 2 diabetes mellitus. In addition, plasma glucose levels increased with plasma RBP-4 quartiles. Similar results were found in the present study.

In the present study, there was consistent increase of visfatin and retinol binding protein-4 in diabetic and control subjects. The good correlation between the increase of visfatin and RBP-4 could indicate a common cause for the increased levels of both parameters, such as increased

visceral obesity. Another explanation is that RBP-4 impairs insulin signaling in skeletal muscle through reduction in insulin-stimulated tyrosine phosphorylation of insulin receptor substrate-1 (IRS-1) at tyrosine residue 612, an important site for the p85 subunit of phosphoinositide3-kinase[12]. Thus increased RBP-4 could lead to insulin resistance, which is followed by a compensatory hypersecretion of visfatin which is known to exert insulin mimetic properties[48].

Visceral and subcutaneous adipose tissue display important metabolic differences. Thus, visceral obesity is mainly associated with obesity-related cardiovascular and metabolic alterations[49]. Indeed, adipocytokines, such as visfatin, are mainly expressed in visceral fat[5]. Therefore, the present study looked at the association of visceral, and subcutaneous, as well as fat deposition in the liver with plasma visfatin and RBP-4 in the studied groups. Visceral fat showed a significant correlation with plasma visfatin levels, whereas, subcutaneous fat, and fatty liver did not show such an association with plasma visfatin levels. Furthermore, according to the results of stepwise multiple regression analysis, plasma visfatin concentrations were correlated with visceral adipose tissue in all the studied groups. This study thus supports the report by Fukuhara et al.[5] that visfatin is associated with visceral fat but not subcutaneous fat, but Berndt et al.[9] did not find an association between plasma visfatin and visceral fat area. A recent study demonstrated that visfatin messenger RNA may be differentially regulated in subcutaneous abdominal and visceral fat [41]. The presence of strong correlation between visfatin and visceral fat confirmed the accuracy of measuring visceral fat by ultrasound rather than by other modalities. Being simple and non invasive, other studies looked for using ultrasound in assessment of visceral fat. This is in agreement with Hirooka et al., [20], who concluded that measurement of visceral fat by ultrasound is as effective as computerized tomography.

Since the liver is the major source of RBP-4 production in rodents and probably also, in humans[50] and because ectopic fat deposition in the liver represents an insulin resistant state[51-53], the present study tested whether circulating RBP-4 is elevated under increased fat accumulation in the liver. Particularly hepatic fat accumulation was found to decrease insulin activation of glycogen synthase and increased gluconeo-enesis, thus, contributing to whole-body insulin resistance[54]. Moreover, prevention of fatty liver[52] and decrease in hepatic fat accumulation were found to decrease insulin resistance[53]. On the other hand, a prior study, revealed a correlation of RBP-4 to waist/hip ratio, suggesting an association between RBP-4 levels and abdominal obesity, however no correlation between RBP-4 levels and percent body fat was found[11,44]. The current study showed that plasma RBP-4 levels did not correlate with visceral or subcutaneous fat but positively correlated with fat deposition in the liver. This is in accordance with the recent study of

Stefan et al.[14] who found that RBP-4 correlated positively with fatty liver but not with visceral or subcutaneous fat. Also, a recent study of Gavi et al.[13] found that serum RBP-4 levels were strongly correlated with the trunk fat and not with peripheral fat[13]. However, in disagreement with the current study, a recent study of Jia et al.[55] showed that serum RBP-4 level was positively correlated with visceral adiposity in Chinese subjects with and without type 2 diabetes mellitus, and subjects treated with rosiglitazone showed reduced visceral fat mass, decreased serum RBP-4 levels and improved insulin sensitivity.

Thus, the close correlations of circulating RBP-4 with fatty liver and insulin resistance may imply that fatty liver is a source of increased RBP-4 production in humans possibly due to the relationship with liver fat and /or due to the stimulatory effects of RBP-4 on gluconeogenesis[12]. In this aspect, circulating RBP-4 might serve as a biomarker of fatty liver.

In conclusion, the present study reported that both plasma visfatin and RBP-4 levels were significantly higher in type 2 diabetics and obese individuals. Regarding body fat distribution, plasma visfatin was found to be strongly correlated with visceral fat only but not with subcutaneous fat, thus suggesting a divergent regulation of this adipokine in different fat depots. These data support that increased visfatin may be a feedback mechanism preventing the deleterious effects of the expansion of the intra-abdominal depots on insulin sensitivity, or simply an epiphenomenon that might be useful as a surrogate marker of increased visceral fat mass and cardiovascular risk. On the other hand, plasma RBP-4 level correlated with insulin resistance and fat deposition in the liver, so, measurement of plasma RBP-4 could become a non-invasive and accessible method for assessing the risks of impaired glucose tolerance, type 2 diabetes mellitus, and cardiovascular disease. Studies of the roles of visfatin and RBP-4 and the amount of visceral fat will shed new light on prevention and treatment of type 2 diabetes, and open a new field for the development of new drugs to improve insulin resistance.

يعتبر النسيج الدهنى مسئولاً عن إفرازات دهنية مختلفة تتعلق بمقاومة الأنسولين وقد يؤدى فهم علاقة تلك الإفرازات بمقاومة الأنسولين إلى تطوير علاجات جديدة لمرض النوع الثانى من البوال السكرى. وقد كان الهدف من هذة الدراسة بحث العلاقة بين الفيزفاتين والبروتين-٤ الرابط للرتينول فى البلازما فى حالة السمنة ومرض البوال السكرى من النوع الثانى، ومن ناحية أخرى بحث العلاقة المباشرة بين هاتين المادتين مع المخزون من النسيج الدهني بواسطة الفحص بالموجات فوق الصوتية.

وقد ضم هذا البحث أربعون مريضاً يعانون من النوع الثانى لمرض البوال السكرى قسموا إلى مجموعتين متساويتين طبقاً لمعاملِ كتلةَ الجسم؛ المجموعة الأولى كَانت من المرضى غير البدناء (معامل كتلة الجسم <٢٥ كجم/ م^{٢}) والمجموعة الأخرى كانت من المرضى البدناءِ (معامل كتلة الجسم >٣٠ كجم/م^{٢}). وكان هناك أيضاً أربعون شخصاً من الأصحاء كمجموعة ضابطة قسموا أيضا إلى مجموعتين متساويتين طبقاً لمعاملِ كتلة الجسم.

أجريت قياسات جسمانية وكيميائية لكل المشاركين مع قياس الفيزفاتين والبروتين-٤ الرابط للرتينول والأنسولين فى البلازما بأستخدام الأنزيم المتعلق لتحليل المواد الماصة المناعية. وتم حساب مؤشر مقاومة الأنسولين بطريقة تقييم التوازن النموذجي. وقدر الدهن فى الأحشاء وتحت الجلد والترسيب الدهنى فى الكبد بواسطة الفحص بالموجات فوق الصوتية.

وقد أظهرت نتائج هذا البحث أن مستويات الفيزفاتين فى البلازما كانت أحصائياً أعلى في مرضى النوع الثانى للبوال السكرى مقارنة بالمجموعة الضابطة ؛ وبالإضافة إلى ذلك كان تركيز الفيزفاتين أعلى بشكل ذى دلالة إحصائية في مرضى النوع الثاني للبوال السكرى البدناء مقارنة بغير البدناء منهم. وبالمثل كانت مستويات البروتين-٤ الرابط للرتينول أحصائياً أعلى بشكل في مجموعة مرضى النوع الثانى للبوال السكرى مقارنة بالمجموعة الضابطة؛ وفى البدناء من مرضى البوال السكرى مقارنة بغير البدناء منهم. وكان هناك علاقة إرتباط ذات دلالة إحصائية إيجابية بين الفيزفاتين والبروتين-٤ الرابط للرتينول ونسبة الخصر إلى الورك ومستوى الأنسولين، ومؤشر مقاومة الأنسولينِ ودهنِ الأحشاء في مرضى النوع الثانى من البوال السكرى، بينما وجدت علاقة إرتباط ذات دلالة إحصائية عكسية بين الفيزفاتين وضغط الدم الإنقباضى. وفى المقابل، وجدت علاقة إرتباط ذات دلالة إحصائية إيجابية بين البروتين-٤ الرابط للرتينول مع معامل كتلة الجسم ونسبة الخصر إلى الورك ومستوى الجلوكوز والأنسولينِ فى الدم ومؤشر مقاومة الأنسولينِ، والكبد الدهنى فى مرضى النوع الثانى من البوال السكرى.

وباستعمال التحليلِ الانحدارى التدريجى اتضح أن الفيزفاتين فى البلازما بقى مرتبطاً إيجابياً بدهنِ الأحشاء ونسبة الخصر إلى الورك في مرضى النوع الثانى من البوال السكرى؛ بينما بقى البروتين-٤ الرابطَ للرتينول فى البلازما مرتبطاً إيجابياً مع معامل كتلة الجسم وترسيب الدهون فى الكبد و مقاومة الانسولين في مرضى النوع الثانى من البوال السكرى.

و يمكن أن نستخلص من هذة الدراسة أن مستويات الفيزفاتين فى البلازما أعلى بشكل ذى دلالة إحصائية فى مرضى النوع الثانى من البوال السكرى مقارنة بالمجموعة الضابطة وهى مرتبطة بالسمنة ودهنِ الأحشاء ولكن ليس بالدهنِ تحت الجلد و بالرغم من زيادة الفيزفاتين في مرض النوع الثانى من البوال السكري إلا أنه مرتبطاً ارتباطاً أولياً بالسمنة. وكذلك نستخلص أ ن مستويات البروتين-٤ الرابط للرتينول فى البلازما متزايدة بشكل ذى دلالة إحصائية في مرضى النوع الثانى من البوال السكرى والسمنة وأن البروتين-٤ الرابط للرتينول لَم يرتبط بدهن الأحشاء أَوالدهن تحت الجلد، لكنه أرتبط إيجابياً بالترسيب الدهنى فى الكبد. ومن هذا نستخلص أن العلاقة الوثيقة بين البروتين-٤ الرابط للرتينول و الترسيب الدهنى فى الكبد ومقاومة الأنسولينِ يمكن أن يعكس التأثيرات القوية للبروتين-٤ الرابط للرتينول على حساسية الانسولين فى الكبد.
